ABSTRACT: We use *in operando* Raman spectroscopy to investigate the structural evolution mechanism of transition metal cation and oxygen anion redox in Li-rich layered oxide cathodes. We directly capture the release of oxygen-driven electrolyte oxidation (especially the dimethyl carbonate component) at high-voltage operation (4.4 V).

Exploring cathode materials with an elevated cutoff voltage is an effective method to access high discharge capacity and energy density.¹ Li-ion batteries (LIBs) powered by Li-rich layered oxides ($\text{Li}_{1+x}\text{TM}_{1-x}\text{O}_2$; TM (transition metal) = Ni, Co, Mn, etc.) have the highest promise regarding energy density (500 Wh kg⁻¹).^{2–5} However, oxidation of O²⁻ anions when charged to a high voltage (usually ~4.4 V vs Li⁺/Li) drives oxygen to escape from the lattice (O-loss).⁶ Molecular O₂ has been detected during the first charge/discharge process by mass spectrometry and gas chromatography.^{7,8} This type of irreversible anion redox is highly correlated with voltage fade, transition metal migration, and electrolyte consumption, resulting in persistent loss of energy density.^{9,10}

The persistent consumption of carbonate-based electrolytes in LIBs operated at high cutoff voltages remains a problem to be addressed. One solution is to replace the carbonate solvent. An alternative is to modify the commercial carbonate electrolyte, such as adding additives in the electrolyte in small amounts.^{11–13} However, questions remain on the origin of electrolyte decomposition, and when such a degradation starts has not been exhaustively studied yet. More importantly, cathode materials may significantly affect electrolyte decomposition, but this point has often been overlooked in battery chemistry.

Here, we report the oxygen-driven electrolyte oxidation mechanism in a typical Li-rich layered oxide, $\text{Li}_{1.2}\text{Ni}_{0.13}\text{Co}_{0.13}\text{-Mn}_{0.62}\text{O}_2$ (LLO), as deduced by *in operando* Raman spectroscopy (Figure S1). To explore the evolution of superoxo species and solvent on charge, we used Raman spectroscopy with a higher resolution than in previous studies.^{5,8,14} The ability of

Raman spectroscopy to provide unique structural information allowed us to directly capture species changes, such as the oxygen reaction intermediate and decomposition of dimethyl carbonate (DMC). We provide direct evidence that oxygen gas, which originates from irreversible oxygen redox of surface lattice oxygen in LLO, drives DMC oxidation during high-voltage cycling (~4.4 V). In particular, DMC signals of LLO (~916 cm⁻¹) decrease almost immediately upon charge (Figures S2a and S3a). The evident weakness of DMC signals is attributed to the partial decomposition of DMC. To find out when the decomposition starts, we carefully evaluated the data.

Interestingly, we found that the decreased DMC signal started around 4.4 V (Figure 1a). It is well-established that O₂ gas is released in Li-rich layered cathodes at ~4.4 V, which is ascribed to the irreversible oxygen redox.^{7,10,15} Now, the DMC decomposition and O₂ release processes can be connected. Therefore, minimizing O₂ release would provide definite proof for the inhibited decomposition of DMC. We introduced an oxygen-deficient NiFe₂O₄ (NFO) coating on the LLO to stabilize the surface lattice oxygen. The phase-compatible NFO coating was previously applied to $\text{Li}_{1.2}\text{Ni}_{0.13}\text{Co}_{0.13}\text{Mn}_{0.54}\text{O}_2$ and showed remarkable ability in suppressing O₂ gas release.⁸ As

expected, we confirmed that O₂ gas is the driving force behind the decomposition of DMC. In particular, a rapid decline of Raman band intensity for DMC was not observed (**Figures 1b, S2b, and S3b**). A pronounced DMC signal in the LLO@NFO2 electrode was observed, and the Raman band intensity was relatively steady, compared to a cliff-like drop around 4.4 V, followed by a low level in the LLO electrode (**Figure S4**). More precisely, the oxidation of O²⁻ at a high voltage plateau (~4.4 V) on charge becomes more reversible after the NFO-coating in LLO@NFO2. Consequently, it is more challenging to trigger the decomposition of DMC.

By comparing *in operando* Raman spectra, the overall structural evolution mechanism from TM cation and oxygen anion redox can be understood. According to Flores et al.,¹⁶ layered LiMO₂ oxides with *R̄3m* space groups can be characterized by two Raman activity modes. As shown in **Figure 2a,d**, in the low wavenumber region (400–680 cm⁻¹), the strong E_g band dominates the spectral characteristics. These bands centered around 517 cm⁻¹ show different behaviors. Specifically, the band gradually weakens in the delithiated state. It disappears in the pristine LLO, while in LLO@NFO2, the intensity of the band remains at a high level during the first cycle. Therefore, we believe that the oxygen environment in the two oxides is different. The M-O-N (M = Ni, Co, Mn from MO₆ octahedra; N = Ni, Fe from NO₆ octahedra) adjusts the local oxygen environment and enhances the redox reversibility of anions. A high level of Mn⁴⁺/Ni²⁺ fraction was observed on charge, suggesting higher M disorder and lattice oxygen activity in LLO@NFO2 (**Figure S4**).^{17,18} The twin peaks centered around 850–880 cm⁻¹ are attributed to O-O vibrations (**Figure 2b,e**).^{19,20} Upon charge, peroxy O-O signals disappear immediately (~4.4 V) in LLO, whereas these signals remain steady in LLO@NFO2. The rapid drop of peroxy O-O signals indicates that peroxides may be oxidized to O₂ gas in LLO. This

finding was further confirmed by *operando* differential electrochemical mass spectrometry (**Figure S5**).

Coupling between irreversible anion redox (oxygen release) and electrolyte decomposition (DMC component) in Li-rich layered oxides has been first visualized by *in operando* Raman spectroscopy. We successfully achieved oxygen-deficient NFO coating on the surface of LLO by a simple solvothermal method, and a strong M-O-N bond was formed at the interface of LLO and NFO coating. The NFO coating stabilizes the lattice oxygen at the interface, improves the reversibility of oxygen in the reaction, and inhibits oxygen precipitation. Our findings provide significant insight into the unsatisfactory electrochemical properties of Li-rich layered oxides at high voltage operating. Accordingly, further studies are needed to develop novel electrolytes for Li-rich layered oxides.
